#### **Lecture 10: Stochastic Bandits**

- Multi-armed bandits
- $\varepsilon$ -greedy
- Upper Confidence Bounds
- Thompson Sampling

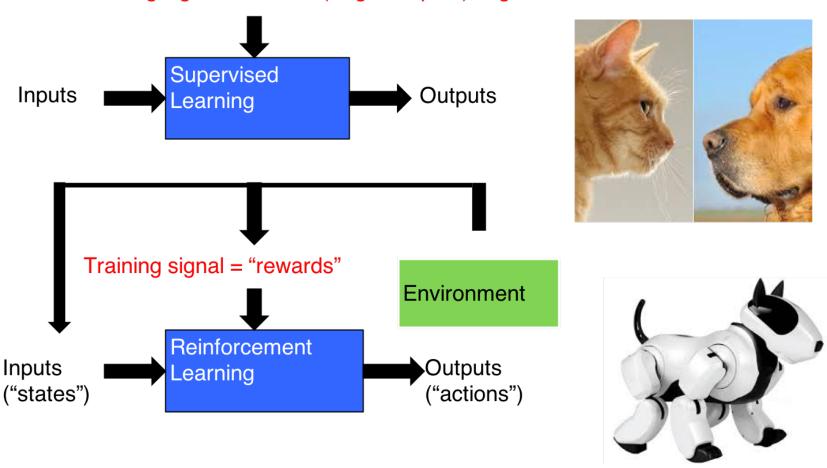

# Reinforcement Learning (RL)

- Learning by trial-and-error, in real time
- Improve with experience
- Inspired by psychology
  - Agent + Environment
  - Agent selects actions to maximize utility function

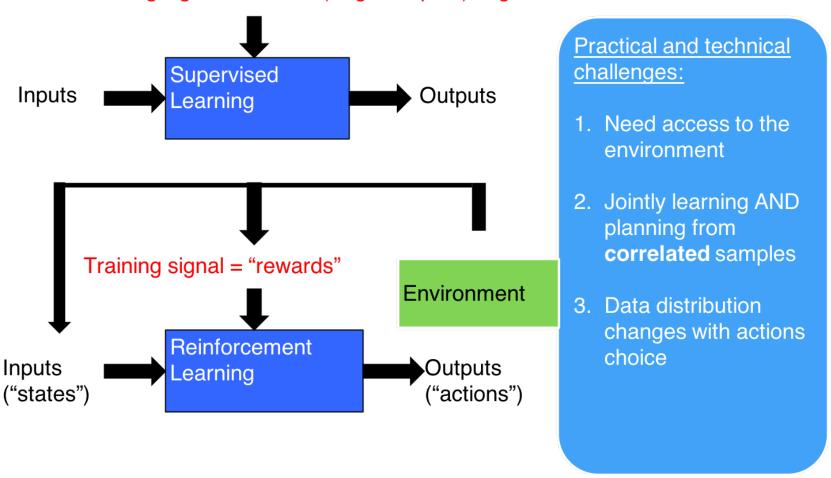

## **RL** vs supervised learning

Training signal = desired (target outputs), e.g. class

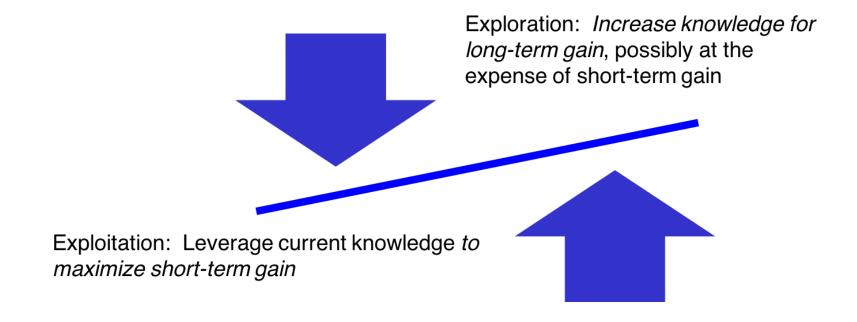

#### **RL** vs supervised learning

Training signal = desired (target outputs), e.g. class

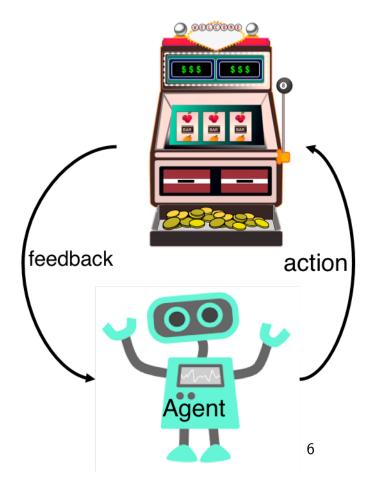

# **Exploration/Exploitation**

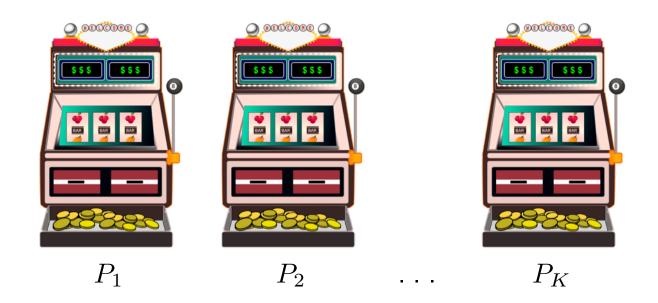

#### Multi-armed bandit

- Named after the original name of slot machines
- Simplified RL setting to focus on exploration/exploitation tradeoff
- Remove the notion of "states"
- Focus on the actions/rewards dynamic

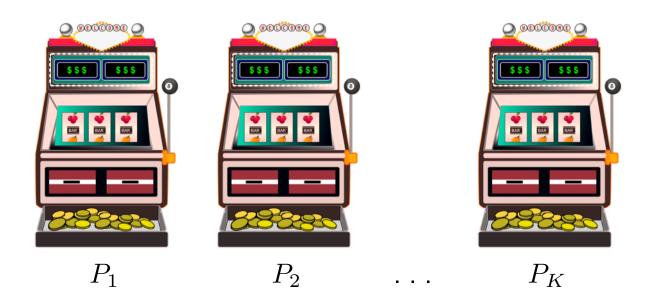

## Bandit setting (Robbins 1952)

- Set  $\mathcal{K} = \{1, 2, \dots, K\}$  of K actions (arms, machines)
- You are facing a tuple of distributions  $\nu = (P_1, P_2, \dots, P_K)$

- Parameters of distributions are unknown ahead of time
- The best action must be determined by interacting with the environment

## Playing a bandit

- $\bullet$  For each round t, choose among the K arms; each choice is called a play
- ullet After each play of machine  $k_t$ , the machine gives a reward  $r_t \sim P_{k_t}$
- ullet The value of action k is its expected reward:  $\mathbb{E}[r_t]$  when  $k_t=k$

Objective: Choose actions in a way that maximizes the reward obtained in the long run (e.g. over 1000 rounds)

## **Application #1: Internet advertising**

- A large Internet company is interested in selling advertising on their website
- It receives money when a company places an ad on the website and that ad gets clicked by a visitor to the website
- What are the bandit's arms?

## **Application #1: Internet advertising**

- A large Internet company is interested in selling advertising on their website
- It receives money when a company places an ad on the website and that ad gets clicked by a visitor to the website
- ullet On a webpage, you can choose to display any of K possible ads
  - Each ad is as an action, with an unknown probability of click rate
  - If the add is clicked, there is a reward, otherwise none

#### Q: What is the best advertisement strategy to maximize return?

Note that this does not require knowledge of the user, the ad content, the webpage content, etc.

#### **Application #2: Network server selection**

- Suppose you can choose to send a job from a user to be processed on one of several servers
- The servers have different processing speed (e.g. due to geographic location, load, etc.
- What are the bandit's arms?

#### **Application #2: Network server selection**

- Suppose you can choose to send a job from a user to be processed on one of several servers
- The servers have different processing speed (e.g. due to geographic location, load, etc.
- Each server can be viewed as an action (arm)
- Over time, you want to learn what is the best action to select
- This is used in routing, DNS server selection, cloud computing, etc.

# **Making decisions**

• Policy:

$$\pi = (\pi_1, \pi_2, \dots)$$

• Probability of playing each action at decision time *t*:

$$\pi_t(k_1, r_1, k_2, r_2, \dots, k_{t-1}, r_{t-1})$$

$$= \Pr[k_t = k | k_1, r_1, k_2, r_2, \dots, k_{t-1}, r_{t-1}] \quad \text{for each } k \in \mathcal{K}$$

# Maximize payoff/minimizing regret

- Maximize cumulative (expected) rewards:  $\mathbb{E}[r_1 + r_2 + \cdots + r_T]$
- Define  $\mu_k(\nu)$  as the expectation of  $P_k$  in configuration  $\nu$
- Optimal action:  $k_{\star}(\nu) = \arg \max_{k \in \mathcal{K}} \mu_k(\nu)$
- Optimal expected reward:  $\mu_{\star}(\nu) = \max_{k \in \mathcal{K}} \mu_k(\nu)$
- Minimize regret:

$$R_T(\pi, \nu) = T\mu_{\star}(\nu) - \mathbb{E}\left[\sum_{t=1}^T r_t\right]$$
$$= T\mu_{\star}(\nu) - \sum_{t=1}^T \mu_{k_t}(\nu)$$

 $\rightarrow$  Comparison of the algorithm with a gold standard

# Example of motivation: Clinical trials (Thompson 1933)

- ullet Available treatments  ${\cal K}$
- For each patient *t*:
  - Recommend treatment  $k_t$
  - Observe treatment response  $r_t$
- $r_t \in \{0,1\}$ : "not cured" vs "cured"
- ullet  $P_k$  is a different Bernoulli distribution for each treatment  $k \in \mathcal{K}$
- Goal: Maximize the number of patients cured

#### The regret

$$R_T(\pi, \nu) = T\mu_{\star}(\nu) - \sum_{t=1}^{T} \mu_{k_t}(\nu)$$

**Lemma 1.** Let  $\nu$  be a stochastic bandit environment. Then,

- 1.  $R_T(\pi, \nu) \ge 0$
- 2. Choosing  $k_t = k_{\star}$  for all t = 1, ..., T satisfies  $R_T(\pi, \nu) = 0$
- 3. If  $R_T(\pi, \nu) = 0$ , then  $k_t$  is optimal with probability 1:  $\Pr[k_t = k_{\star}] = 1$
- Point 3 is only achievable if we know  $k_{\star}$  in  $\nu$
- ullet In general, we only know that  $u \in \mathcal{E}$  for some environment class  $\mathcal{E}$
- ullet Relatively weak objective: find a policy  $\pi$  with sublinear regret

$$\forall \nu \in \mathcal{E}, \quad \lim_{T \to \infty} \frac{R_T(\pi, \nu)}{T} = 0$$

## **Decomposing the regret**

- Suboptimality gap:  $\Delta_k(\nu) = \mu_{\star}(\nu) \mu_k(\nu)$
- Number of plays of action k up to time t:  $N_k(t) = \sum_{s=1}^t \mathbb{I}\{k_s = k\}$
- $\rightarrow$  In general,  $N_k(t)$  is random: policy  $\pi$  is based on random observations

**Lemma 2.** For any policy  $\pi$  and K-armed stochastic bandit environment  $\nu$  and horizon  $T \in \mathbb{N}$ , the regret  $R_T$  of policy  $\pi$  in  $\nu$  satisfies

$$R_T = \sum_{k \in \mathcal{K}} \Delta_k \, \mathbb{E}[N_k(T)]$$

*Proof.* Using that  $\sum_{k \in \mathcal{K}} \mathbb{I}\{k_t = k\} = 1$  we have

$$R_{T} = T\mu_{\star} - \mathbb{E}\left[\sum_{t=1}^{T} r_{t}\right] = \sum_{t=1}^{T} \mathbb{E}\left[\mu_{\star} - r_{t}|k_{t}\right]$$

$$= \sum_{t=1}^{T} \sum_{k \in \mathcal{K}} \mathbb{E}\left[(\mu_{\star} - r_{t})\mathbb{I}\{k_{t} = k\}|k_{t}\right]$$

$$= \sum_{t=1}^{T} \sum_{k \in \mathcal{K}} (\mu_{\star} - \mu_{k_{t}}) \mathbb{E}\left[\mathbb{I}\{k_{t} = k\}|k_{t}\right]$$

$$= \sum_{t=1}^{T} \sum_{k \in \mathcal{K}} (\mu_{\star} - \mu_{k}) \mathbb{E}\left[\mathbb{I}\{k_{t} = k\}|k_{t}\right]$$

$$= \sum_{t=1}^{T} \Delta_{k} \sum_{t=1}^{T} \mathbb{E}\left[\mathbb{I}\{k_{t} = k\}|k_{t}\right]$$

#### **Estimating action values**

 Then we can estimate the value of the action as the sample average of the rewards obtained:

$$\hat{\mu}_k(t) = \frac{\sum_{s=1}^t r_s \mathbb{I}\{k_s = k\}}{N_k(t)}$$

- By law of large numbers:  $\lim_{N_k(t)\to\infty}\hat{\mu}_k(t)=\mu_k$
- On the one hand, you want to exploit the knowledge you have, which means picking the greedy action:

$$k_t = \arg\max_{k \in \mathcal{K}} \hat{\mu}_k(t-1)$$

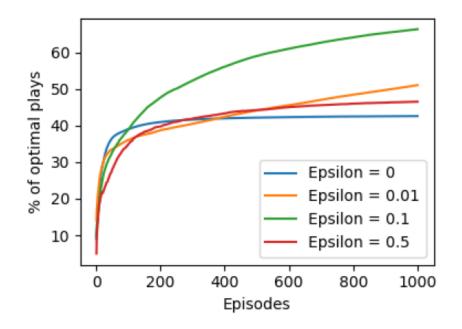

# **Exploration/Exploitation tradeoff**

- On the other hand, you need to explore actions, that is to figure out which one is best (which means some amount of random choice)
- ullet Exploration only: Choose each action T/K times
  - → Optimal action is played as much as worst action
- Always choose action  $k_t = \arg \max_{k \in \mathcal{K}} \hat{\mu}_k(t-1)$ 
  - $\rightarrow$  Risk of converging to a suboptimal action

So how and when should we explore?

#### $\varepsilon$ -greedy: A simple strategy

- Pick exploration constant  $\varepsilon \in [0,1]$ , usually small (e.g.  $\varepsilon = 0.1$ )
- Explore with probability  $\varepsilon$ : select action  $k_t$  uniformely at random
- Exploit with probability  $1-\varepsilon$ : selection action  $k_t = \arg\max_{k \in \mathcal{K}} \hat{\mu}_k(t-1)$
- Worst action is played (on expectation)  $T\varepsilon/K$  times after T rounds

Problem: Linear regret!

## $\varepsilon$ -greedy: Sublinear regret

**Theorem 1** (Auer at al. 2002). *Solution: Decrease*  $\varepsilon$  *with time* 

- Consider reward distributions with bounded support in [0, 1]
- Let  $\Delta = \min_{k \in \mathcal{K}, k \neq k_{\star}} \Delta_k$

For  $\varepsilon_t = \min\left\{\frac{6K}{\Delta^2T}, 1\right\}$ , there exists a constant C > 0 such that the probability of playing a suboptimal action is bounded by  $\frac{C}{\Delta^2t}$ . As a consequence, for any suboptimal action k, it holds that

$$\mathbb{E}[N_k(T)] \le \sum_{t=1}^T \frac{C}{\Delta^2 t} \le \frac{C}{\Delta^2} \ln T$$

and thus

$$R_T \le \sum_{k \in \mathcal{K}} \Delta_k \frac{C}{\Delta^2} \ln T$$

#### $\varepsilon$ -greedy: Weaknesses

- ullet Theoretical guarantee requires the knowledge of  $\Delta$
- $\rightarrow$  In practice: Decrease  $\varepsilon$  with time (e.g. 1/t,  $1/\sqrt{t}$ , . . . ) What is the good rate?
  - Exploration makes suboptimal choices: It explores all actions equally
- $\rightarrow$  Problem especially important for K>2

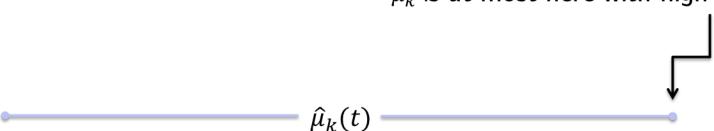

Idea: Explore based on information needed

#### **Confidence intervals**

E.g. Chernoff-Hæffding For  $r_t \in [0,1]$ :

$$\Pr\left[\mu_k - \hat{\mu}_k(t) \ge \varepsilon\right] \le \exp\left(-\frac{N_k(t)\varepsilon^2}{2}\right) \quad \text{or} \quad \Pr\left[\mu_k \ge \hat{\mu}_k(t) + \sqrt{\frac{2\ln(1/\delta)}{N_k(t)}}\right] \le \delta$$

 $\mu_k$  is at most here with high confidence

ightarrow Confidence interval reduces as we gain information about the action

# **Upper Confidence Bounds (UCB)**

$$UCB_k(t, \delta) = \hat{\mu}_k(t) + \sqrt{\frac{2\ln(1/\delta)}{N_k(t)}}$$

- ullet Input: Number of actions K, confidence level  $\delta$
- Play each action once
- For episodes t > K: Select action  $k_t = \arg \max_{k \in \mathcal{K}} UCB_k(t-1, \delta)$

Key observation: After the initial plays of each action, action k can only be selected at time t+1 if  $UCB_k(t,\delta) \geq UCB_{\star}(t,\delta)$ . This requires at least one of the following:

- a)  $UCB_k(t, \delta) \ge \mu_{\star}$
- b) UCB<sub>\*</sub> $(t, \delta) \leq \mu_*$

## **UCB:** Bounding suboptimal plays

$$\mathbb{E}[N_k(T)] \le 1 + \mathbb{E}\left[\sum_{t=1}^T \mathbb{I}\{\text{UCB}_k(t-1) \ge \mu_{\star}\}\right] + \mathbb{E}\left[\sum_{t=1}^T \mathbb{I}\{\text{UCB}_{\star}(t-1) \le \mu_{\star}\}\right]$$

$$\le 1 + \sum_{t=1}^T \Pr\left[\text{UCB}_k(t-1) \ge \mu_{\star}\right] + \sum_{t=1}^T \Pr\left[\text{UCB}_{\star}(t-1) \le \mu_{\star}\right]$$

**UCB:** 
$$UCB_k(t, \delta) \geq \mu_{\star}$$

$$\hat{\mu}_k(t) + \sqrt{\frac{2\ln\frac{1}{\delta}}{N_k(t)}} \ge \mu_{\star}$$

$$\hat{\mu}_k(t) + \sqrt{\frac{2\ln\frac{1}{\delta}}{N_k(t)}} - \mu_k \ge \underbrace{\mu_{\star} - \mu_k}_{\Delta_k}$$

$$\hat{\mu}_k(t) - \mu_k \ge \underbrace{\Delta_k - \sqrt{\frac{2\ln\frac{1}{\delta}}{N_k(t)}}}_{c\Delta_k} \Rightarrow N_k(t) = \frac{2\ln\frac{1}{\delta}}{\Delta_k^2(1-c)^2}$$

$$\Pr\left[\hat{\mu}_k(t) - \mu_k \ge \Delta_k - \sqrt{\frac{2\ln\frac{1}{\delta}}{N_k(t)}}\right] \le \exp\left(-\frac{N_k(t)c^2\Delta_k^2}{2}\right) = \delta^{c^2/(1-c)^2}$$

for 
$$N_k(t) \ge \frac{2\ln\frac{1}{\delta}}{\Delta_k^2(1-c)^2}$$

# **UCB:** UCB<sub>\*</sub> $(t, \delta) \leq \mu_*$

- $\Pr\left[\hat{\mu}_{\star}(t) + \sqrt{\frac{2\ln\frac{1}{\delta}}{N_{\star}(t)}} \leq \mu_{\star}\right]$  depends on  $N_{\star}(t)$  (explicitly and in  $\hat{\mu}_{\star}(t)$ )
- Explicit  $\hat{\mu}_{\star,u}(t) = \hat{\mu}_{\star}(t)$  s.t.  $N_{\star}(t) = u$
- $N_{\star}(t)$  is a random variable that could take any value  $s \in \{1, \ldots, t\}$

Look at

$$\Pr\left[\min_{s=1...t} \hat{\mu}_{\star,s}(t) + \sqrt{\frac{2\ln\frac{1}{\delta}}{s}} \le \mu_{\star}\right] \le \Pr\left[\bigcup_{s=1...t} \hat{\mu}_{\star,s}(t) + \sqrt{\frac{2\ln\frac{1}{\delta}}{s}} \le \mu_{\star}\right]$$

$$\le \sum_{s=1}^{t} \Pr\left[\hat{\mu}_{\star,s}(t) + \sqrt{\frac{2\ln\frac{1}{\delta}}{s}} \le \mu_{\star}\right]$$

$$\le t\delta$$

# **UCB:** Bounding suboptimal plays (cont'd)

$$\mathbb{E}[N_{k}(T)] \leq 1 + \mathbb{E}\left[\sum_{t=1}^{T} \mathbb{I}\{\text{UCB}_{k}(t-1) \geq \mu_{\star}\}\right] + \mathbb{E}\left[\sum_{t=1}^{T} \mathbb{I}\{\text{UCB}_{\star}(t-1) \leq \mu_{\star}\}\right]$$

$$\leq 1 + \sum_{t=1}^{T} \Pr\left[\text{UCB}_{k}(t-1) \geq \mu_{\star}\right] + \sum_{t=1}^{T} \Pr\left[\text{UCB}_{\star}(t-1) \leq \mu_{\star}\right]$$

$$\leq 1 + \left[\frac{2\ln\frac{1}{\delta}}{\Delta_{k}^{2}(1-c)^{2}}\right] + \sum_{t=1}^{T} \delta^{c^{2}/(1-c)^{2}} + \sum_{t=1}^{T} t\delta$$

$$\Rightarrow \sum_{t=1}^{T} t\delta \le 1 \text{ for } \delta = 1/T^2$$

$$\Rightarrow \sum_{t=1}^{T} \delta^{c^2/(1-c)^2} = \sum_{t=1}^{T} T^{-2c^2/(1-c)^2} = T^{1-2c^2/(1-c)^2}$$

# UCB: Bounding suboptimal plays (cont'd)

$$\mathbb{E}[N_k(T)] \le 1 + \left\lceil \frac{2\ln T^2}{\Delta_k^2 (1-c)^2} \right\rceil + T^{1-2c^2/(1-c)^2} + 1$$

- $\Rightarrow$  Polynomial dependence on T unless  $2c^2/(1-c)^2 \ge 1$
- $\Rightarrow$  First term blows up if  $c \rightarrow 1$
- $\Rightarrow$  Arbitrarily pick c = 1/2

**Theorem 2.** Consider UCB on a stochastic K-armed 1-subgaussian bandit problem. For any horizon T, if  $\delta = 1/T^2$  then

$$\mathbb{E}[N_k(T)] \le \frac{16 \ln T}{\Delta_k^2} + 3$$

$$R_T \le \sum_{k \in \mathcal{K}, k \ne k_*} \frac{16 \ln T}{\Delta_k} + 3 \sum_{k \in \mathcal{K}} \Delta_k$$

## **UCB: Summary**

- Well understood
- Natural proof
- Has been extended to many bandits variants
- $\rightarrow \ \text{Requires confidence intervals}$

## **Thompson Sampling: A Bayesian intuition**

- Select next action based on its probability of being optimal
- Observations obtained with action k:  $X_{k,1}, X_{k,2}, \ldots, X_{k,N_k(t)}$

$$\underbrace{\Pr\left[\mu_{k}|X_{k,1},X_{k,2},\ldots,X_{k,N_{k}(t)}\right]}^{\text{posterior}} = \underbrace{\frac{\Pr\left[X_{k,1},X_{k,2},\ldots,X_{k,N_{k}(t)}|\mu_{k}\right]}{\Pr\left[X_{k,1},X_{k,2},\ldots,X_{k,N_{k}(t)}|\mu_{k}\right]}}^{\text{prior}}_{\Pr\left[\mu_{k}\right]}$$

#### **Conjugate priors**

- When prior and posterior have the same form
- Provides a closed-form expression for the posterior
- All members from the exponential family have conjugate priors:

- Gaussian: Gaussian

- Bernoulli: Beta

- Poisson: Gamma

- Multinomial: Dirichlet

# **Example: Beta-Bernoulli**

- Bernoulli e.g. head/tail
- Parameter p: probability of success (1)
  - -(1-p): probability of failure
  - $-\mu = p$
- Posterior on  $\mu$  after N observations:

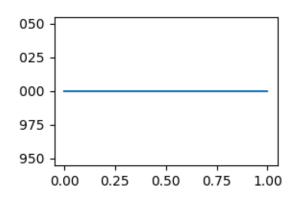

Beta 
$$\left(\begin{array}{c} \alpha_0 + \sum_{n=1}^N X_n \\ \end{array}, \beta_0 + N - \sum_{n=1}^N X_n \right)$$

•  $\alpha_0$  and  $\beta_0$  are priors

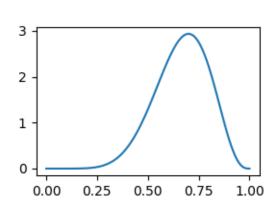

## **Example: Beta-Bernoulli posterior evolution**

- Typical priors:  $\alpha_0 = \beta_0 = 1$ : Uniform priors
- Example:  $\mu = 0.75$

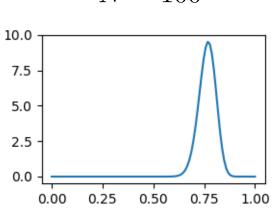

$$N = 0$$

$$N = 10$$

$$N = 100$$

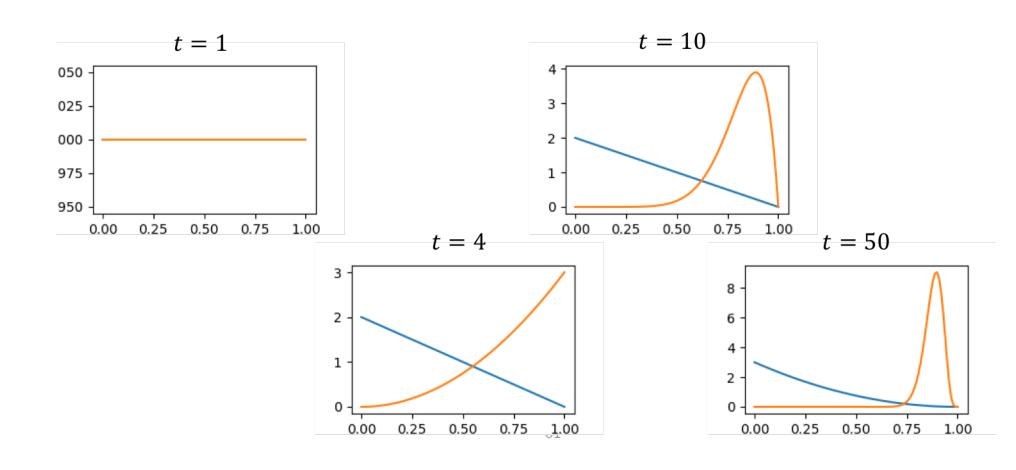

## **Thompson Sampling**

- ullet Maintain one posterior  $\pi_t^{(k)}$  for each action  $k \in \mathcal{K}$
- At time *t*:
  - Sample one value  $\theta_k \sim \pi_t^{(k)}$  for each action  $k \in \mathcal{K}$
  - Select action  $k_t = \arg\max_{k \in \mathcal{K}} \theta_k$
- Stochastic policy
  - Good for parallel runs
  - Good for delayed feedback
- Exploration reduces as posterior tightens

## **Example: Thompson Sampling on 2-arms**

• Bernoulli rewards (head/tails, win/loss) with  $\mu_1 = 0.9$   $\mu_2 = 0.1$ 

# **Thompson Sampling analysis**

- Frequentist analysis is much more technical than UCB
- Frequentist analysis depends on prior

**Theorem 3.** If Thompson Sampling is run on a Gaussian bandit  $\nu \in \mathcal{E}_{\mathcal{N}}^{K}$ , then

$$R_T \le C \sum_{k \in \mathcal{K}} \Delta_k + \sum_{k \in \mathcal{K}, k \ne k_{\star}} C \frac{\ln T}{\Delta_k}$$

for some universal constant C > 0.

- In practice, TS has better regret than standard UCB
- There exists variants of UCB that have better regret and less variance (in practice) than TS

#### **Summary**

- Many algorithms, many *similar* regret bounds (in terms of order)
- Similar regret bounds do not necessarily mean similar performance in practice
- UCB depends on the tightness of confidence intervals
- TS depends on how fast the posterior converges
- Stochasticity in the policy can be good or bad
- Both UCB and TS have been extended to different bandits variants

#### **Synthetic experiments**

```
import numpy as np
means = np.array([0.1, 0.9])
regrets = np.max(means) - means
K = len(means)
alg = TS_Bernoulli(nb_arms=K, a0=1, b0=1)
cumul_regrets = [0]
for t in range(1000):
    k_t = alg.select()
    r_t = np.random.rand() < means[k_t]
    alg.update(k_t, r_t)
    cumul_regrets.append(cumul_regrets[-1]+regrets[k_t])
```
